Abstract

This paper explores the skilled tasks demanded by Chilean exporting firms. Production involves many different tasks and tasks are executed by workers with different skills. Some tasks are skill-intensive, while others are unskilled-intensive. Firms produce goods of varying quality and exporters tend to produce higher quality goods. In turn, the production of quality is intensive in skilled-intensive tasks. Finally, firms are heterogenous and more productive firms become exporters and have a higher demand for skilled workers in skilled tasks. We provide evidence in support of these theories using the Chilean Encuesta Nacional Industrial Anual (ENIA), an annual census of manufacturing firms. We show that Chilean exporters utilize more skills than Chilean non-exporters and we show that exporters require the services of skilled specialized workers as opposed to skilled administrative workers. In addition, exporters demand less unskilled labor in unskilled-intensive tasks.

JEL CODES: F13, F14
Key Words: firm behavior and exports, skilled labor and trade, specialized workers in exports

1 Introduction

This paper explores the skilled tasks demanded by Chilean exporting firms. We build on a framework that combines various strands of recent trade literature. Production involves many different tasks, such as managing, accounting, clerical activities, design, packaging, logistics, sales representation, operational production, input control, monitoring, supervision, services. Tasks are executed by workers with different skills, some tasks are skill-intensive, while others are unskilled-intensive. Firms produce goods of varying quality and exporters tend to produce higher quality goods. In turn, the production of quality is intensive in some, but not necessarily all, skilled-intensive tasks. Firms are heterogeneous and differ in the efficiency of factor use: some firms are more productive in skill-intensive tasks than others. More productive firms become exporters and hire more skilled workers overall. The demand for skilled workers will, however, be biased towards those skilled tasks required to produce exportable goods. Using a panel of Chilean firm, we document these mechanisms.

A strand of recent trade theories postulates the higher quality of exporting goods and studies the implications for wage inequality and the demand for skills. Verhoogen (2008) shows that exports in Mexico are associated with a higher skilled composition of employment because firms upgrade product quality, a task that is intensive in skills. Using Argentine firm-level data, Brambilla, Lederman and Porto (2012) argue that exporting per se may not necessarily lead to higher skill utilization but, rather, that what matters is the destination of a firms' exports. In particular, for developing countries, exporting to high-income countries requires skills but exporting per se does not. This is because firms need to increase product quality, as in Verhoogen (2008), and because firms need to use skilled labor to execute exports, as in Matsuyama (2007). In a panel of Latin American countries, Brambilla, Dix-Carneiro, Lederman, and Porto (2011) document that the intensity of an industry's exports is positively correlated with the skill premium paid in such industry. Finally, Bastos, Silva and Verhoogen (2014) establish a positive causal link between

Empirically, Autor, Levy and Murnane (2003) and Ebenstein, Harrison, McMillan and Phillips

where M is market size and W is an index that summarizes the characteristics of all available products in that market (i.e. $W = \sum_{z \in Z} \exp(\delta_z$

services or building maintenance; at the top of the ranking, we can find engineering activities, product testing and so on.

Equations (4) are Ricardian task production functions. To determine the assignment of skills to tasks, we assume that wages are exogenous to the firm. The wage paid to one skilled worker is w_H and the wage paid to one unskilled worker is w_L. In an equilibrium, which resembles the many-good comparative advantage chain, there is a cutoff task i_x such that all tasks $i_x < i_x$ are produced exclusively by unskilled workers, and $i_x \geq i_x$ are instead performed by skilled workers. To see this, note that, given the fixed coefficient technology and the exogenous factor prices, unskilled and skilled workers never share tasks, that is, it is optimal to allocate skilled workers to some tasks and unskilled workers to different ones. The cutoff task is determined by the equality of the unit cost of producing i_x with either skilled and unskilled workers

$$(5) \quad \frac{w_L}{a_{Lx}(i_x)} = \frac{w_H}{a_{Hx}(i_x)}.$$

Given that tasks are ranked in decreasing order or unskilled intensity, it follows that, for $i < i_x$, $w_H/a_{Hx}(i) > w_L/a_{Lx}(i)$ and thus all these tasks are filled with unskilled labor. The numbers of employees in each of these tasks is

$$(6) \quad l_x(i) = \frac{y_x(i)}{a_{Lx}(i)}; \; h_x(i) = 0.$$

By contrast, for $i \geq i_x$, $w_H/a_{Hx}(i) < w_L/a_{Lx}(i)$ so that it is relatively cheaper to use skilled labor to perform these tasks. The numbers of employees in each $i \geq i_x$

$$(7) \quad l_x(i) = 0; \; h_x(i) = \frac{y_x(i)}{a_{Lx}(i)}.$$

We work out the solution for skilled and unskilled labor demand below, but for the moment, note that the cost function associated with the production function (3) is given by

$$(8) \quad c = \exp \int_0^1 \ln p_x(i) di;$$

where $p_x(i)$ is the implicit price of task i in physical production. These prices are given by

$$(9) \quad w_L = p_x(i) a_{Lx}(i);$$

marginal cost of quality.[4] As before, $y(i)$ is the services of task i in quality production and tasks are performed by skilled workers H or unskilled workers L with production functions

(14) $y\ (i$

choices of quality and price to maximize profits.[5] The objective function is

$$(19)\quad \ = (p \quad c)x(p;\ ) \quad F(\ ).$$

The first order conditions are

$$(20)\quad p = 1 + c;$$

$$(21)\quad x(p;\ ) = F'(\ ).$$

In this simple setting, thus, firms charge the same price for goods of any quality. This price is a markup over the marginal cost c (given by (8)). Since it is costly to produce quality, vertical differentiation occurs because firms can sell higher quantities of higher-quality products. The optimal choice of quality is determined by the equality of the marginal cost ($F'(\ )$) and the marginal benefit (higher sales measured by $x(p;\ )$) of quality provision. For an interior solution, we assume that the marginal cost increases in at a sufficiently high rate (concretely, the second order condition for profit maximization is $F''(\ ) > \ ^2x(p;\ )$). The equilibrium choice of quality is depicted, ceteris paribus, in Figure 3.

To end, we explore the differences between firms, and between exporters and non-exporters, and we lay out the implications of these differences across firms for the demand for skilled tasks. To streamline the exposition, we assume firms only differ in , the quality productivity factor. (Firms could also differ in , the efficiency in skill utilization, or in the factor prices they face.) From the first order conditions for profit maximization, a higher implies a higher optimal quality provision (which in virtue of the fixed markup is sold at the same price $p = 1 + c$). In Figure 3, the marginal cost of quality production shifts down because of the higher productivity, and the firm can profitably increase quality at the optimum.

To look at the role of exporting, we assume, as it is standard in the trade-quality literature, that export markets demand higher quality and that firms need to incur a fixed cost of exporting. As a consequence, higher firms can afford to cover this fixed cost because of the higher quality of their products. This result is typically subsumed with the determination of a productivity cutoff $_{min}$ so

[5] See Brambilla and Porto (2014) for a literature review and various alternative specifications of the theory of quality and exports.

that rms with $> {}_{min}$ become exporters and rms with $< {}_{min}$ only ll the domestic market.[6] This means that, on average, exporters produces higher quality products than non-exporters. In addition, within exporters, rms with higher quality-productivity will ship a larger share of their sales abroad and will produce even higher quality output.

For our purpose in the empirical work of section 3, we need to work out the implications for the demand of skilled tasks. Equations (6) and (7) determine the utilization of unskilled and skilled labor in production task i, while equations (16) and (17) determine the utilization of unskilled and skilled labor in quality provision task i. In the Chilean data, we have information on employment of skilled and unskilled workers in various activities and tasks, but we do not necessarily know the fraction of employment of each type of worker in output or in quality production. We just know aggregate employment across tasks. For this reason, we now study the implications of the model at an aggregate level.

and

$$(26)\quad h\ (i) = h\ = \frac{(F(\ )}{w_H}:$$

This means that all unskilled *quality production* tasks are performed by the same number of unskilled employees, and all *quality production* skilled tasks are similarly performed by the same number of skilled employees.

It is useful to plot relative skilled utilization for di erent tasks i. We do this is Figure 2. For the lowest skill tasks, $i < i$, only unskilled workers are utilized, both for output production and for quality production. This could be the case of cleaning or simple maintenance tasks. For the highest skill tasks, $i > i_x$, only skilled workers are utilized. This can re ect activities such as machine supervision, software development and so on. For intermediate tasks, $i < i < i_x$, unskilled workers are utilized in output production and skilled workers in quality production. This can refer to an engineer, who monitors production, and a trainee, that operates machines. Figure 2 shows how the share of total skilled employment is increasing in tasks i. Moreover, as rms become more productive (i.e., have a higher) and choose to produce higher quality , the share of skilled labor utilization increases. In this simple nr0f-37simple, In b .s 9..ng-3896ororIn.9091 Tf 3.758 0 Td [(.)3(share)-
aggreg-585(247fTd [(mis2462-471(i)1(s83(ta7ks)]T462/F54summtasks2462across25247fn.909o)-2(b)- -2T5(tast)-2(sup)-to)-471(plo

and that

$$(30)\quad H = \frac{F(\ )}{w_H}(1 \quad i \ ):$$

Clearly, from expressions (27)-(30), higher productivity rms are larger in that they hire more employees of any skill in any tasks. This is because of two factors. High productivity rms can a ord to produce higher quality goods which requires both skilled and unskilled labor. In turn, a higher quality product has a higher total demand and producing physical units also requires both types of labor. To get more meaningful testable implications from the model, the result that we want to emphasize is that as grows higher, rms expand skilled labor disproportionately more than unskilled labor. To see this, let total unskilled labor L be the sum of unskilled labor in production and in quality, $L = L_x + L$; let total skilled labor H

need to show that $@ \; =@ \;\; > \;\; = \;$. Using the rst order condition (21), we nd that

$$(34) \quad \frac{@}{@} = -\frac{1}{1} > -:$$

The intuition underneath this result is that, even though has cost-saving e ects, the resulting choice of higher quality in equilibrium induces an su ciently large increase in total quality provision costs.

Going back to the employment e ect (31), note that, given that quality production is intensive in skills relative to physical output production ($H \; =H > L \; =L$), this quality provision e ect implies that more productive rms expand skilled labor relatively more than unskilled labor.

By contrast, the model also implies that higher quality boosts output

$$(35) \quad \frac{@ \ln x}{@} = \frac{@}{@} > 0;$$

and, consequently, given the factor intensities, there is an output production e ect whereby more productive rms expand unskilled labor relatively more than skilled labor.

In the model, it turns out that the e ect on employment of higher quality provision dominates the e ect of higher output production. Indeed, if $\; > 0$, then,

$$(36) \quad \frac{@ \ln F(\;)}{@} \quad \frac{@ \ln x}{@} = \frac{1}{\;} \frac{@}{@} \quad \frac{1}{\;} \quad \frac{@}{@} > 0:$$

To conclude then, we have shown that increases in productivity lead to increases in skilled labor relative to unskilled labor utilization. This is because high-productivity rms need to expand quality and production, but quality is more intensive in skilled tasks. Furthermore, higher productivity rms can also a ord to export their output because being more pro table, they can cover the xed costs of exporting. In the end, exporting rms have a larger demand for skilled tasks than non-exporting rms and, in addition, higher export intensity among exporters is also associated with higher demand for skilled tasks.

Another interesting implication of the theory is that the type of tasks in which the increase in skills takes place. Tasks are ranked in decreasing order of skill intensity so that the most skilled-intensive tasks are always performed by skilled labor both in exporters and in non-exporters. For instance, this implies less signi cant di erences in the characteristics of managers or CEOs across export intensity. A firm exporting most of its output may hire similar management than a firm exporting half of its output or than a firm exporting very little. The differences in skilled utilization will most likely take place in interior of the task space. We interpret this result as suggesting a higher utilization of specialized workers, such as engineers, chemists, designers. Similarly, the theory predicts less significant differences in unskilled utilization in the most unskilled intensive tasks, i.e., cleaning, maintenance, repairs. By contrast, in marginal blue-collar unskilled tasks, exporters may hire more workers with more skills, with more expertise or tenure.

3 Evidence on Exports and The Demand for Skilled Tasks

In this section, we investigate the tasks demanded by Chilean exporters. We first describe the data and present the basic correlations between skills, tasks, and exports. Then, we introduce our econometric model where we explore causality behind the underlying correlations. To this end, we rely on an instrumental variable approach where we use changes in exchange rates faced by Chilean exports in world markets as exogenous variation in export exposure of Chilean firms.

3.1 The Chilean Data

We use two sources of data, firm-level data and customs records. The firm-level data come from the Encuesta Nacional Industrial Anual (ENIA), an annual industrial census run by Chile's Instituto Nacional de Estadística that interviews all manufacturing plants with 10 workers or more. It is a panel. The customs data provide administrative records on firms exports by destination. We manually matched both databases for the period 2001-2005. As a result, we built a 5-year panel database of Chilean manufacturing firms.

The data have several modules. The main module contains information on industry affiliation, ownership type, sales, exports, input use, imports of materials, workers and wages. Industry affiliation is defined at the 4-digit ISIC Revision 3 level, which makes up for a total of 113 industries.

We are mostly interested in the employment information. The data on workers are presented at detailed categories, which allows us to explore the demand for different skills and tasks. From the detailed employment records, we define the following tasks: management (directors), administrative services (accountants, lawyers), engineers (specialized skilled production workers), blue-collar activities (non-specialized unskilled production workers), and general maintenance services (unskilled non-production workers). The first three categories, managers, administrative workers, and engineers, comprise skilled labor. To enrich the analysis, we also define a highly-skilled group, which includes managers and engineers. Unskilled workers are blue-collar, non-specialized and general maintenance workers. In turn, production workers include engineers and blue-collar operatives, while non-production workers include managers, administrative workers and maintenance workers.

Table 1 briefly presents some key summary statistics for the key variables in our model. We present the unconditional averages as well as averages for exporting firms and non-exporting firms. On average, Chilean firms hire 39 percent of skilled workers and 61 percent of unskilled workers. As expected, exporters utilize a higher share of skilled workers (41 percent) than non-exporters (39 percent). Exporters are also larger and they hire, on average, more workers in all skilled categories than non-exporters. Employment of unskilled workers in also higher among exporters, but only marginally. Production workers account for 73 percent of employment of all Chilean firms, and of 70 percent of the employment of exporters. In addition, exporters employ more

Figure 4 shows that exports are positively associated with skilled employment and negatively correlated with unskilled employment. Moreover, we nd separate positive correlations with highly skilled employment as well as with skilled employment more generally. In turn, Figure 5 shows that higher export intensity is associated with higher employment of both production and non-production workers.

In Figure 6, we learn that, within skilled labor, exports demand more engineers (specialized workers) and services (accounting, IT), but not necessarily managers. In Figure 7, we learn that, within unskilled labor, exports demand less blue-collar workers and maintenance services (janitors, repair workers) in general. In addition, for production, exports demand engineers over blue-collars (Figure 8), while, for non-production, exports demand services more than maintenance workers (Figure 9).

3.3 Regression Results

We now set out to study the correlations outline above with formal regression models. We rst want to explore if the correlations are robust to other correlates and, second, to test for causality. To do this, we expand our mode as follows

(38) $y_{ijt} = x'_{ijt} \quad + \quad E_{ijt} + \quad {}_{i} + \quad {}_{jt} + \quad {}_{ijt};$

where indices i and t are as above and j is an industry. We add the vector x, which includes rm level variables such as log total employment, log sales, and initial conditions (sales and exporting status) interacted with year dummies to account for rm-speci c trends. The regression includes rm xed e ects, ${}_{i}$ and industry year e ects, ${}_{jt}$.

Before turning to causality, we explore the correlations with these extended OLS-FE estimation. Results are in Table 2. In column 1, we show the basic correlation corresponding to the graphs above. These regressions only include export intensity, rm xed-e ects and year-e ects and we report them for consistency with the graphical analysis. For the rst robustness experiment, in column 2, we add log employment to control for size. This means we compare rms of equal size, with di erent export intensity. As it can be seen, the correlation between exports and highly-skilled and skilled employment is positive and statistically signi cant. The results show that a rm with 10 percentage points higher export intensity hire 1.9 percent more highly-skilled workers and 1.6

percent higher skilled workers than a similar-size firm. Exporters tend to hire less unskilled labor, but this coefficient is weak statistically. In terms of specific tasks, we find that exports hire more engineers and administrative service workers and hire less maintenance service workers. There are no statistically discernible difference in managerial and unskilled blue-collar employment.

These correlations may be driven by industry trends, such as industry-specific growth processes. To account for those trends, we add in column 3 interactions between year dummies and industry dummies. The results are robust. In column 4, we also add initial conditions to account for firm-specific trends (Brambilla, Lederman, and Porto, 2012). The results are also very robust. The magnitudes of the coefficients are also stable across specifications.

While these correlations are very robust, they are still correlations, not necessarily causal effects. To get to these causal effects, we need to instrument the variable E_{ijt}. This is because, for instance, there might be omitted variables creating biases. More productive firms are, for example, more likely to export and, at the same time, be more efficient in the use of skilled labor. To build instruments, we follow a strategy similar to Revenga (1992), Revenga (1997), Bastos, Silva and Verhoogen (2014), Brambilla, Lederman and Porto (2012), Brambilla and Porto (2014), and Park et al. (2010), among others. Intuitively, the argument runs as follows. Exogenous export opportunities for a firm are likely to arise when its foreign export markets expand. In turn, this will happen when the income of the destination country grows and when exchange rate changes make Chilean exports relatively cheaper. Given any of these exogenous changes, a firm will be more likely to take advantage of these export opportunities if it is exposed to those markets. A natural measure of destination exposure in this case is the share of a firm's exports to that destination in total firm sales. Formally, we define two instruments

$$(39)\quad z^0_{jt} = \sum_d s_{dj} \ln g_{dt};$$

and

$$(40)\quad z^1_{jt} = \sum_d s_{dj} \ln r_{dt};$$

where z^0 and z^1 are the instruments, s_{dj} is the share of exports of firm j to export destination d at the initial time period (year 2001), g_{dt} is the real GPD of destination d at time t, and r_{dt} is the bilateral exchange rate between Chile and country d at t. Hence, z^0_{jt} and z^1_{jt} are weighted averages of the real gdp and the real exchange rate face by Chilean exporters, where the firm-specific weights are the initial shares of exports in sales. As in Brambilla, Lederman and Porto (2012), we also interact z^0 and z^1 with initial firm sales (i.e., log sales in 2001) to include any firm advantages in profiting from export opportunities based on firm size. To assess the power of these instruments, we can look at the first stage results for the same four specifications used in the OLS-FE model. The results are in Table 3. As it can be seen, the instruments have a lot of explanatory power in this first stage. They also easily satisfy the test of joint significance. The real GDP of the export destination market appears to be a stronger determinant of export intensity than the real exchange rate. However, it is the combination of all these instruments together that performs very well and we consequently use this specification in what follows.

The causal impacts of export intensity of employment are reported in Table 4. Conditional on size, firms that export a higher share of their total sales utilize more skilled (and also highly-skilled) workers, and less unskilled workers. This implies that exporters need to perform skill intensive activities and tasks. By contrast, there are not discernible causal impact of exports on production or non-production employment. This means that, ceteris paribus, a firm utilizes roughly the same type of production and non-production workers to produce goods for exports or for the local domestic market.

Among skilled workers, exporters utilize significantly more engineers (specialized workers), conditional on size. However, employment of specialized service workers tends to be higher but this is not statistically significant. Similarly, managerial employment is relative smaller as exports grow, but not significantly so (statistically). Among unskilled workers, the bulk of the difference takes place among non-specialized blue-collar workers.

Table 5 reports results using shares of employment, instead of log employment. We confirm that the share of skilled labor is statistically higher among exporters. The share of highly-skilled workers is also higher. Instead, the shares of production and non-production workers are not statistically different. The share of engineering employment is much higher among exports. This is compensated with lower shares of blue-collar employment, while the shares of all other types of employments are not statistically different.

4 Conclusions

In this paper, we have explored the link between exports and the demand for skilled tasks in Chile. Chilean exports require skills. Foreign consumers value product quality and are willing to pay for it. In turn, quality is intensive in skilled labor. As a consequence, exporters demand more skilled workers relative to unskilled workers. However, exports do not necessarily require any skill. In particular, exporting leads to a more intensive use of skilled tasks in the production process. This leads to a higher demand of engineers vis-a-vis unskilled workers (blue-collar or maintenance services workers) as well as non-production skilled workers (administrative services workers). We have developed a simple partial equilibrium model to formalize these mechanisms and we have provided evidence from a panel of Chilean firms in support of the model.

Notes: First-stage results of IV-FE regressions of (log) employment on export intensity (exports/sales). Column (1): rm xed-e ects and year xed-e ects; column (2): adds log total employment (rm size); column (3): adds controls for industry-speci c trends (i.e., interactions between year dummies and industry dummies); column (4): adds initial conditions to control for rm-speci c trends. Data are from the Encuesta Nacional Industrial Anual (National Annual Industrial Survey), Chile 2001-2005.
